1. Introduction

Ast is a generator for program modules that define the structure of abstract syntax trees and provide general tree manipulating procedures. The defined trees may be decorated with attributes of arbitrary types. Besides trees, graphs can be handled, too. The structure of the trees is specified by a formalism based on context-free grammars. The generated module includes procedures to construct and destroy trees, to read and write trees from (to) files, and to traverse trees in some commonly used manners. The mentioned readers and writers process text as well as binary tree representations. Most procedures work for graphs as well.

The advantages of this approach are: record aggregates are provided which allow a concise notation for node creation. It is possible to build trees by writing terms. An extension mechanism avoids chain rules and allows, for example lists with elements of different types. Input/output procedures for records and complete graphs are provided. The output procedures and the interactive graph browser facilitate the debugging phase as they operate on a readable level and know the data structure. The user does not have to care about algorithms for traversing graphs. He/she is freed from the task of writing large amounts of relatively simple code. All of these features significantly increase programmer productivity.

Ast is implemented in Modula-2 as well as in C. The tool generates C, C++, Java, or Modula-2 source code. Two versions of C++ source code can be generated which will be called simple C++ and proper C++ in this document. Simple C++ uses for the representation of the tree nodes the same data structure as C: A union type of a set of struct types. Only one class is used whose members are the data items which are global variables in C. Proper C++ uses class types and inheritance for the representation of the tree nodes. Global variables are still used as in C.

The following sections define the specification language, explain the generated output, discuss related approaches, and present some examples.

2. Specification Language

The structure of trees and directed graphs is specified by a formalism based on context-free grammars. However, we primarily use the terminology of trees and types in defining the specification language. Its relationship to context-free grammars is discussed later.

2.1. Node Types

A tree consists of nodes. A node may be related to other nodes in a so-called parent-child relation. Then the first node is called a parent node and the latter nodes are called child nodes. Nodes without a parent node are usually called root nodes, nodes without children are called leaf nodes.

The structure and the properties of nodes are described by node types. Every node belongs to a node type. A specification for a tree describes a finite number of node types. A node type specifies the names of the child nodes and the associated node types as well as the names of the attributes and the associated attribute types. A node type is introduced by a name which can be an identifier or a string. The names of all node types have to be pairwise distinct. A node type can be regarded as a nonterminal, a terminal, or an abstract entity. Nonterminals are characterized by the character ‘=’ following its name, terminals by the character ‘:’, and abstract node types by the characters ’:=’. Undefined node types are implicitly defined to be terminals without attributes. The distinction between nonterminals and terminals is only of interest if concrete syntax is described. In the case of abstract syntax this distinction does not make sense and therefore nonterminal node types and eventually abstract ones suffice. Abstract node types are explained in section 2.6.
Example:

```
If = .
While = .
'()' = .
Ident : .
"==" : .
SCOPE := .
```

The example defines the node types *If*, *While*, and `()'` to be nonterminals, the node types *Ident* and `"=="` to be terminals, and *SCOPE* to be an abstract node type.

The following names are reserved for keywords and can not be used for node types:

```
BEGIN CLOSE DECLARE DEMAND END
EVAL EXPORT FOR FUNCTION GLOBAL
IGNORE IMPORT IN INH INHERITED
INPUT LEFT LOCAL MODULE NONE
OUT OUTPUT PARSER PREC PROPERTY
REMOTE REV REVERSE RIGHT RULE
SCANNER SELECT STACK START SUBUNIT
SYN SYNTHESIZED THREAD TREE VIEW
VIRTUAL VOID
```

### 2.2. Children

Children describe subtrees. They are distinguished by *selector* names which have to be unambiguous within one node type. A child has a certain node type.

Example:

```
If = Expr: Expr Then: Stats Else: Stats .
While = Expr: Expr Stats: Stats .
```

The example introduces two node types called *If* and *While*. A node of type *If* has three children which are selected by the names *Expr*, *Then*, and *Else*. The children have the node types *Expr*, *Stats*, and *Stats*.

If a selector name is equal to the associated name of the node type it can be omitted. Therefore, the above example can be abbreviated as follows:

```
If = Expr: Expr Then: Stats Else: Stats .
While = Expr Stats: Stats .
```

### 2.3. Attributes

Besides children, every node type can specify an arbitrary number of *attributes* of arbitrary types. Like children, attributes are characterized by a selector name and a certain type. The descriptions of attributes are enclosed in brackets. The types for attributes are given by names taken from the target language or from the set of node types. The type of an attribute can be the general tree pointer types `tTREE` and `TREE`, too. Missing types are assumed to be `int` or `INTEGER` depending on the target language (C, C++, Java, or Modula-2). Children and attributes can be given in any order.

If the type of an attribute is a node type, `tTREE`, or `TREE`, the attribute is called tree-valued, otherwise it is not tree-valued. By default, `ast` does not follow a tree-valued attribute during a graph
Ast

traversal. All attributes are considered to be neither tree nor graph structured. Only the user knows about this fact and therefore he/she should take care. Exceptions are the graph browser procedure DrawTREE/Draw which can launch a separate browser on a subtree rooted at a tree-valued attribute and the tree transformation tool puma which does type checking for tree-valued attributes. In some cases this default treatment of tree-valued attributes can be changed in such a way that they are treated like children (see description of the procedure ConfigureTREE/Configure).

Example (in C or C++):

```
IntConst = [Value] .
RealConst = [Value: float] .
```

For example the node types IntConst and RealConst describe leaf nodes with an attribute named Value of types int or float respectively. Binary and Unary are node types with an attribute called Operator of type int.

Example (in C or C++):

```
Node = [a1: Binary] [a2: Tree] [a3: tTree] [a4: int] .
```

The attributes a1, a2, and a3 are tree-valued, while the attribute a4 is not tree-valued.

2.4. Declare Clause

The DECLARE clause allows the definition of children and attributes for several node types at one time. Following the keyword DECLARE, a set of declarations can be given. The syntax is the same as described above with the exception that several node type names may introduce a declaration. If there already exists a declaration for a specified node type, the children and attributes are added to this declaration. Otherwise a new node type is introduced.

Example:

```
DECLARE
  Decls Stats Expr = [Level] [Env: tEnv] .
  Expr = Code [Type: tType] .
```

2.5. Extensions

To allow several alternatives for the types of children an extension mechanism is used. A node type may be associated with several other node types enclosed in angle brackets. The first node type is called base or super type and the latter types are called derived types or subtypes. A derived type can in turn be extended with no limitation of the nesting depth. The extension mechanism induces a subtype relation between node types. This relation is transitive. Where a node of a certain node type is required, either a node of this node type or a node of a subtype thereof is possible.

Example:

```
Stats = <
  If = Expr Then: Stats Else: Stats .
  While = Expr Stats .
> .
```
In the above example *Stats* is a base type describing nodes with neither children nor attributes. It has two derived types called *If* and *While*. Where a node of type *Stats* is required, nodes of types *Stats*, *If*, and *While* are possible. Where a node of type *If* is required, nodes of type *If* are possible, only.

Besides extending the set of possible node types, the extension mechanism has the property of extending the children and attributes of the nodes of the base type. The derived types possess the children and attributes of the base type. They may define additional children and attributes. In other words they *inherit* the structure of the base type. The selector names of all children and attributes in an extension hierarchy have to be distinct. The syntax of extensions has been designed this way in order to allow single inheritance, only. Multiple inheritance is available, too. It is described in the next section.

Example:

```
Stats = Next: Stats [Pos: tPosition] <
If = Expr Then: Stats Else: Stats .
While = Expr Stats .>
```

Nodes of type *Stats* have one child selected by the name *Next* and one attribute named *Pos*. Nodes of type *While* have three children with the selector names *Next*, *Expr*, and *Stats* and one attribute named *Pos*.

A node of a base type like *Stats* usually does not occur in an abstract syntax tree for a complete program. Still, *ast* defines this node type. It could be used as placeholder for unexpanded nonterminals in incomplete programs which occur in applications like syntax directed editors.

### 2.6. Multiple Inheritance

The extension mechanism described in the previous section allows for single inheritance of children and attributes. The syntax of the extensions has been designed to reflect the notation of context-free grammars as close as possible. For multiple inheritance a different syntax and the concept of *abstract node types* are used.

Abstract node types are characterized by the definition characters `':=' instead of `':=' or `':` which are used for nonterminals or terminals. They are termed abstract because they describe only the structure of nodes or parts thereof but nodes of this types do not exist. Therefore no code is generated by *ast* for abstract node types: no constant, no record type, no constructor procedure, etc.. Abstract node types can only be used as base types in combination with multiple inheritance.

For multiple inheritance the following syntax is used: The name of a node type may be followed by a left arrow `':-` and a list of names. This construct is available for all three kinds of node types: nonterminals, terminals, and abstract node types. The names after the left arrow have to denote abstract node types. The meaning is that the node type inherits the structure of all listed abstract node types. Multiple inheritance is possible from abstract node types to non abstract ones and among abstract node types. Among non abstract node types only single inheritance is allowed.
Example:

```plaintext
DECLS := [Objects: tObjects THREAD] <
  NODECLS := .
  DECL := [Ident: tIdent INPUT] Next:DECLS .
> .
ENV := [Env: tEnv INH] .
USE <- ENV := [Ident: tIdent INPUT] [Object: tObject SYN] .
SCOPE <- ENV := [Objects: tObjects SYN] [NewEnv: tEnv SYN] .

Root = Proc .
Decl <- DECL =<
  Var = .
  Proc <- SCOPE = Decls Stats .
> .
Stat = <
  Assign = Name Expr .
  Call <- USE = .
> .
Expr <- ENV =<
  Const = [Value] .
  Name <- USE = .
> .
```

The above example uses multiple inheritance and abstract node types to describe the identification problem of programming languages. The node types written with all upper-case letters represent abstract node types. DECLS specifies lists of declared objects, SCOPE describes scopes or visibility regions, ENV stands for environment and is used to distribute scope information, and USE is intended to be used at the application of identifiers. In the second part of the example, the abstract node types are connected to nonterminal node types. Decls is the concrete node type to describe lists of declarations. Decl represents one declaration and there are two alternatives, Var and Proc, variables and procedures. A procedure introduces a scope and therefore it inherits from SCOPE. At the node types Call and Name identifiers are used and thus they inherit from USE. Finally, the node types Decls, Stats, and Expr are regions where the environment information has to be distributed and they inherit from ENV.

### 2.7. Modules

The specification of node types can be grouped into an arbitrary number of modules. The modules allow to combine parts of the specification that logically belong together. This feature can be used to structure a specification or to extend an existing one. A module consists of target code sections (see section 2.13.) and specifications of node types with attribute declarations. The information given in the modules is merged in the following way: the target code sections are concatenated. If a node type has already been declared the given children, attributes, and subtypes are added to the existing declaration. Otherwise a new node type is introduced. This way of
modularization offers several possibilities:

- Context-free grammar and attribute declarations (= node types) can be combined in one module.
- The context-free grammar and the attribute declarations can be placed in two separate modules.
- The attribute declarations can be subdivided into several modules according to the tasks of semantic analysis. For example, there would be modules for scope handling, type determination, and context conditions.
- The information can be grouped according to language concepts or nonterminals. For example, there would be modules containing the grammar rules and the attribute declarations for declarations, statements, and expressions.

Example:

```plaintext
MODULE my_version
Stats = [Env: tEnv] < /* add attribute */
    While = Init: Stats Terminate: Stats . /* add children */
    Repeat = Stats Expr . /* add node type */
> .
END my_version
```

### 2.8. Properties

The description of children and attributes can be refined by the association of so-called properties. These properties are expressed by the keywords listed in Table 1.

The properties have the following meanings: Input attributes (or children) receive a value at node-creation time, whereas non-input attributes may receive their values at later times. Output attributes are supposed to hold a value at the end of a node’s existence, whereas non-output attributes may become undefined or unnecessary earlier. Synthesized and inherited describe the kinds of attributes occurring in attribute grammars. They have no meaning for ast. The property thread supports so-called threaded attributes: An attribute declaration [a THREAD] is equivalent to the declaration of a pair of attributes with the suffixes In and Out: [aIn] [aOut]. These attributes have to be accessed with their full name including the suffixes. The property reverse specifies how lists should be reversed. It is discussed in section 2.12. The property ignore instructs ast to disregard or omit an attribute or a child. It is useful in connection with the concept of views (see section

<table>
<thead>
<tr>
<th>Property</th>
<th>Long Form</th>
<th>Short Form</th>
</tr>
</thead>
<tbody>
<tr>
<td>INPUT</td>
<td>IN</td>
<td></td>
</tr>
<tr>
<td>OUTPUT</td>
<td>OUT</td>
<td></td>
</tr>
<tr>
<td>SYNTHESIZED</td>
<td>SYN</td>
<td></td>
</tr>
<tr>
<td>INHERITED</td>
<td>INH</td>
<td></td>
</tr>
<tr>
<td>THREAD</td>
<td></td>
<td></td>
</tr>
<tr>
<td>REVERSE</td>
<td>REV</td>
<td></td>
</tr>
<tr>
<td>IGNORE</td>
<td></td>
<td></td>
</tr>
<tr>
<td>VIRTUAL</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
2.10.). The property \textit{virtual} is meaningful in attribute grammars. It is used to describe dependencies among attributes. However, no space will be allocated for those attributes and the attribute computations for those attributes will be omitted in the generated attribute evaluator. Within \textit{ast} the properties \textit{input}, \textit{reverse}, and \textit{ignore} are of interest, only.

Properties are specified either locally or globally. Local properties are valid for one individual child or attribute. They are listed after the type of this item. Example:

\begin{verbatim}
Stats = Next: Stats IN REV [Pos: tPosition IN] [Level INH]
\end{verbatim}

Global properties are valid for all children and attributes defined in one or several modules. They are valid in addition to the local properties that might be specified. In order to describe global properties, a module may contain several property clauses which are written in the following form:

\begin{verbatim}
PROPERTY properties [ FOR module_names ]
\end{verbatim}

The listed properties become valid for the given modules. If the FOR part is missing, the properties become valid for the module that contains the clause.

Example:

\begin{verbatim}
PROPERTY INPUT
PROPERTY SYN OUT FOR Mapping
\end{verbatim}

Input attributes without initializer expression (see section 2.16.) are included into the parameter list of the node constructor procedures (see section 3). The global property \textit{input} replaces the symbol ‘\textit{->}’ of former versions of \textit{ast}. For compatibility reasons this symbol still works in a restricted way: The symbol ‘\textit{->}’ could be included in a list of children and attributes as a shorthand notation to separate input from non-input items. In a list without this symbol all children and attributes are treated as input items. This meaning of the symbol ‘\textit{->}’ is still in effect as long as \textit{ast} does not encounter a global property clause. After encountering such a clause, local and global properties are in effect only – the symbol ‘\textit{->}’ is ignored.

Example:

\begin{verbatim}
Stats = Next: Stats REV [Pos: tPosition] -> [Level INH] <
If = Expr Then: Stats Else: Stats .
While = -> Expr IN Stats IN .
> .
\end{verbatim}

The node types of the example possess the children and attributes listed in Table 2.

\subsection*{2.9. Subunits}

Usually, an \textit{ast} specification is translated into one program module. This module receives the name that immediately follows the keyword TREE. If several modules contain a name, the first one is chosen. If none of the modules contains a name, the default name \textit{Tree} is used. For target languages C, C++, and Modula it is possible to generate several modules out of an \textit{ast} specification. Then there is exactly one module called \textit{main unit} that describes the tree structure and an arbitrary number of modules called \textit{subunits}. This is of interest if the generated source code becomes too large for one compilation unit. Then either some or all desired procedures could be placed into separate subunits. In the extreme, there might be a subunit for every procedure. It is possible to have two or more versions of one procedure (e. g. \textit{WriteTREE}) where every one uses a different view

(see section 2.10.).

The names of the main unit and the subunits are described in the header of an _ast_ specification:

```plaintext
[ TREE [ Name [ PREFIX Name ] ] ] [ SUBUNIT Name ] [ VIEW Name ]
```

The name after the keyword VIEW is necessary if abstract syntax trees are to be processed by program modules generated with other tools such as e.g. _puma_ [Groa] that need to know the definition of the tree structure. _Ast_ has an option that requests to write a binary version of the tree definition to a file whose name is derived from the name given after the keyword VIEW by appending the suffix ".TS" (Default: "Tree.TS").

Every unit has to be generated by a separate run of _ast_. If a subunit name is present, then a subunit is generated – otherwise a main unit is generated. The options select the procedures to be included in the units. It is probably wise not to include the subunit name in an _ast_ specification. If this name is added "on the fly" with UNIX commands then different subunits can be generated from one specification without the need to change it.

Example:

```plaintext
ast -dim spec.ast
echo SUBUNIT read | cat - spec.ast | ast -dir
```

or

```plaintext
ast -dim spec.ast
echo TREE MyTree SUBUNIT read | cat - spec.ast | ast -dir
```

2.10. Views

An _ast_ specification can be roughly seen as a collection of node types and associated children and attributes. A so-called _view_ selects a subset of this collection and it may attach further
properties to some parts of this collection. In the current version of \texttt{ast}, views are not available if the target language is Java.

The concept of views is necessary for instance if two programs communicate a common data structure via a file. Every program might need additional data which should neither appear in the other program nor in the file. In order to make this work both programs must agree upon the coding of the node types in the shared part of the data structure. This is accomplished by using one common \texttt{ast} specification that contains the description of the complete data structure. Every program uses a specific view and selects only those parts of the common specification that are of interest. See Figure 1 for an example.

![Diagram of program sharing a part of a data structure]

UNIX commands to generate the compilation units:

\begin{verbatim}
  echo SELECT A C | cat - spec.ast | ast -dim
  echo SUBUNIT PutTree SELECT C | cat - spec.ast | ast -dip
  echo SELECT B C | cat - spec.ast | ast -dim
  echo SUBUNIT GetTree SELECT C | cat - spec.ast | ast -dig
\end{verbatim}

Fig. 1: Programs Sharing a Part of a Data Structure
Another need for views arises if several attribute evaluators operate one after the other on one tree. The output attributes of a preceding evaluator become the input attributes of a succeeding one. Here it is necessary to be able to change the properties of attributes. In one view the attributes are regarded as output and in the other one they are regarded as input. The usage of views for the specification of several attribute evaluators is described in [Grob].

Furthermore, views are necessary if abstract syntax trees are to be processed by program modules generated with other tools such as e.g. *puma* [Groa] that need to know the definition of the tree structure. In general, there might be several tree processing modules and every one uses a different view. In this case, the views have to be communicated to the other tool in a file. *ast* has an option that requests to write a binary version of the tree definition to a file whose name is derived from the name given after the keyword VIEW by appending the suffix ".TS" (Default: "Tree.TS", see section on "Subunits").

The concept of views is based on the global properties:

```
PROPERTY properties FOR module_names
```

allows the dynamic addition of properties.

```
PROPERTY IGNORE FOR module_names
```

allows the suppression of all definitions given in the listed modules. Additionally there is the so-called select clause:

```
SELECT module_names
```

This is equivalent to:

```
PROPERTY IGNORE FOR module_names_not_given
```

It is wise to assign names to all modules of an *ast* specification, because otherwise they can not be selected with the select clause. Furthermore, the property or select clauses that express views should probably not be included in the file containing the *ast* specification. The reason is that this form is not flexible, because it is relatively hard to change. It is better to add the one line that is necessary for views "on the fly" using UNIX commands like echo and cat (see Figure 1).

### 2.11. Prefixing

A prefix can be added to the generated names that are derived from the names of the node types. This mechanism for prefixing is available for the languages C and simple C++. An *ast* specification can describe a prefix after the keyword PREFIX in addition to the name for a tree specification using the following syntax:

```
[ TREE [ Name [ PREFIX Name ] ] ]
```

The prefix is added to the following kinds of generated names:
<table>
<thead>
<tr>
<th>generated name</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>k&lt;prefix&gt;&lt;node type&gt;</td>
<td>named constant to encode a node type in C and C++</td>
</tr>
<tr>
<td>&lt;prefix&gt;&lt;node type&gt;</td>
<td>name of union member for a node type</td>
</tr>
<tr>
<td>n&lt;prefix&gt;&lt;node type&gt;</td>
<td>node constructor procedures with attribute initialization according to the type specific operations or an initializer expression</td>
</tr>
<tr>
<td>m&lt;prefix&gt;&lt;node type&gt;</td>
<td>node constructor procedures with attribute initialization from a parameter list for input attributes without initializer expression</td>
</tr>
</tbody>
</table>

Example:

```c
TREE sql_tree PREFIX sql_ RULE
stmt = <
    declare_stmt = ... .
    select_stmt = ... .
> .
```

The generated code will include the following declarations:

```c
// named constants
#define ksql_declare_stmt 2
#define ksql_select_stmt 3

// constructor procedures
extern tTree msql_declare_stmt (...);
extern tTree msql_select_stmt (...);
```

Note, the tools `ag` and `puma` are aware of the prefix. Therefore, in the specifications for these tools the node types are written without prefix. The prefix is generated automatically by these tools.

### 2.12. Reversal of Lists

Recursive node types like `Stats` in the abstract grammar of the example below describe lists of subtrees. There are at least two cases where it is convenient to be able to easily reverse the order of the subtrees in a list. The facility provided by `ast` is a generalization of an idea presented in [Par88].

#### 2.12.1. LR Parsers

Using LR parsers, one might be forced to parse a list using a left-recursive concrete grammar rule because of the limited stack size. The concrete grammar rules of the following examples are written in the input language of the parser generator `Lark` [Groc] which is similar to the one of Yacc [Joh75]. The node constructor procedures within the semantic actions are the ones provided by `ast` (see section 3).
Example:

concrete grammar (with tree building actions):

```
Stats: {$$ = mStats0 (); }.
Stats: Stats Stat ';;' {$$ = mStats1 ($2, $1);} .
Stat : WHILE Expr DO Stats END {$$ = mWhile ($2, $4);} .
```

abstract grammar:

```
Stats =<
  Stats0 = .
  Stats1 = Stat Stats .
> .
```

A parser using the above concrete grammar would construct statement lists where the list elements are in the wrong order, because the last statement in the source would be the first one in the list. The WHILE rule represents a location where statement lists are used.

To easily solve this problem ast can generate a procedure to reverse lists. The specification has to describe how this should be done. At most one child of every node type may be given the property reverse. The child’s type has to be the node type itself or an associated base type. The generated list reversal procedure ReverseTREE then reverses a list with respect to this indicated child. The procedure ReverseTREE has to be called exactly once for a list to be reversed. This is the case at the location where a complete list is included as subtree (e. g. in a WHILE statement).

Example:

concrete grammar (with tree building actions):

```
Stats: {$$ = mStats0 (); }.
Stats: Stats Stat ';;' {$$ = mStats1 ($2, $1);} .
Stat : WHILE Expr DO Stats END {$$ = mWhile ($2, ReverseTREE ($4));} .
```

abstract grammar:

```
Stats =<
  Stats0 = .
  Stats1 = Stat Stats REVERSE .
> .
```

It is possible to represent lists differently in an abstract syntax. A more sophisticated solution is given in the next example. The procedure ReverseTREE handles this variant, too.
Example:

concrete grammar (with tree building actions):

```plaintext
Stats:  ($$ = mNoStat ();) .
Stats: Stats IF Expr THEN Stats ELSE Stats END ';'
      ($$ = mIf ($3, ReverseTREE ($5), ReverseTREE ($7), $1)); .
Stats: Stats WHILE Expr DO Stats END ';'
      ($$ = mWhile ($3, ReverseTREE ($5), $1)); .
```

abstract grammar:

```plaintext
Stats = <
   NoStat = .
   Stat = Next: Stats REVERSE <
          If = Expr Then: Stats Else: Stats .
          While = Expr Stats .
   > .
> .
```

2.12.2. LL Parsers

Using LL parsers a similar problem as in the LR case can arise if extended BNF is used. Lists are parsed with an iteration which is turned into a loop statement as follows: (The identifiers Stats0, Stats1, Stat0, and Stat1 in the concrete grammar rules denote the symbolic access to the L-attribute mechanism provided by Ell [GrV]. These identifiers should not be mixed up with the similar ones used as node names in the abstract syntax.)

Example:

concrete grammar (with tree building actions):

```plaintext
Stats: (*Stats0=mStats0 ();) ( Stat ';' (*Stats0=mStats1 (Stat1, Stats0)); ) * .
Stat : WHILE Expr DO Stats END (*Stat0=mWhile (Expr1, ReverseTREE (Stats1));) .
```

abstract grammar:

```plaintext
Stats = <
   Stats0 = .
   Stats1 = Stat Stats REVERSE .
> .
```

The list elements (statements) are inserted in the wrong order within the first concrete grammar rule. The order is corrected by a call of the procedure ReverseTREE in the second concrete grammar rule.

2.13. Target Code

An ast specification may include several sections containing so-called target code. These sections follow the keywords TREE or SUBUNIT. Target code is code written in the target language which is copied uncheckeed and unchanged to certain places in the generated module. It has to be enclosed in braces '{' '}’. Balanced braces within the target code are allowed. Unbalanced braces have to be escaped by a preceding '\' character. In general, the escape character '\' escapes everything within target code. Therefore, especially the escape character itself has to be escaped.

The meaning of the sections is as follows:
IMPORT: references to other target language modules, for example to provide definitions of types for attribute declarations.

EXPORT: declarations to be included in addition to the declaration of the tree type.

GLOBAL: declarations to be included in the implementation module at global level. This is where to put macro definitions to select code generation options.

LOCAL: same as GLOBAL within ast for C and Modula. For C++ see below.

BEGIN: initialization statements.

CLOSE: finalization statements.

The exact use of these sections varies according to the target language, as discussed below.

2.13.1. C and C++

The meaning of the sections is as follows:

IMPORT: #include directives or typedef declarations to be included in the header file.

EXPORT: declarations to be included in the header file after the declaration of the tree type tTREE.

GLOBAL: declarations to be included in the implementation module at global level.

LOCAL: In C: the same as GLOBAL.
In simple C++: member declarations to be included in the class declaration.
In proper C++: declarations to be included at namespace level.

BEGIN: statements to initialize the declared data structures.

CLOSE: statements to finalize the declared data structures.

Example in C or C++:

TREE SyntaxTree
IMPORT { # include "Idents.h" }  
EXPORT { typedef tSyntaxTree MyTree; }  
GLOBAL { # include "Idents.h"  
    typedef struct { unsigned Line, Column; } tPosition; }  
BEGIN { ... }  
CLOSE { ... }
2.13.2. Modula-2

The meaning of the sections is as follows:

IMPORT: declarations to be included in the definition module at a place where IMPORT statements are legal.

EXPORT: declarations to be included in the definition module after the declaration of the tree type \( tTREE \).

GLOBAL: declarations to be included in the implementation module at global level.

BEGIN: statements to initialize the declared data structures.

CLOSE: statements to finalize the declared data structures.

Example in Modula-2:

```modula2
TREE SyntaxTree
IMPORT { FROM Idents IMPORT tIdent; }
EXPORT { TYPE MyTree = tSyntaxTree; }
GLOBAL { FROM Idents IMPORT tIdent;
  TYPE tPosition = RECORD Line, Column: CARDINAL; END; }
BEGIN { ... }
CLOSE { ... }
```

2.13.3. Java

The meaning of the sections is as follows:

IMPORT: If no IMPORT sections are present \( ast \) includes import statements for classes in the reuse package. If an IMPORT section is present then a statement equivalent to the following should be included:

```java
import de.cocolab.reuse.*;
```

EXPORT: additional members to be included in the TREE class.

GLOBAL: macro definitions to select code generation options.

BEGIN: statements to be executed when the TREE class is loaded.

CLOSE: statements to be executed when the TREE.close () method is called.

Example in Java:

```java
TREE SyntaxTree
IMPORT { import de.cocolab.reuse.*;
  import com.package.*; }
EXPORT { public int member; }
GLOBAL { # define readMyType(a) ... }
BEGIN { ... }
CLOSE { ... }
```

2.14. Common Node Fields

Sometimes it is desirable to include certain fields into all node types. For languages except Java this can be done directly by defining the macro \( TREE_NodeHead \) in the IMPORT or EXPORT target code sections. For Java, use the GLOBAL target code section. In C, simple C++, and Modula these fields become members of the union member or variant named \( yyHead \). In proper C++ and Java these fields become members of the common super class. They can be accessed as shown in
the following examples:

Example in C or simple C++:

```c
#define Tree_NodeHead int MyField1; MyType MyField2;
t->yyHead.MyField1 = ... ;
```

Example in proper C++:

```c
#define Tree_NodeHead int MyField1; MyType MyField2;
t->MyField1 = ... ;
```

Example in Modula-2:

```c
#define Tree_NodeHead MyField1: INTEGER; MyField2: MyType;
t^.yyHead.MyField1 := ... ;
```

Example in Java:

```c
#define Tree_NodeHead public int MyField1; public MyType MyField2;
t.MyField1 = ... ;
```

Macros may be defined to process these additional fields during tree operations (see Table 3). These macros are fully implemented only for C, C++, and Java. They are similar to the type specific operations described in the next section except that the argument is a reference to the node rather than a reference to an individual attribute.

<table>
<thead>
<tr>
<th>operation</th>
<th>macro name</th>
<th>purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>initialization</td>
<td>beginNodeHead(a)</td>
<td>initialize values during node creation</td>
</tr>

</tbody>
</table>

Note: In Java, the function of binary read/write is achieved via the serialization facility.

2.15. Type Specific Operations

Procedures generated by `ast` apply several operations to attributes: initialization, finalization, text read and write, binary read and write, copy, test for equality, and XML output (see Table 4). *Initialization* is performed whenever a node is created. It can range from assigning an initial value to the allocation of dynamic storage or the construction of complex data structures. *Finalization* is performed immediately before a node is deleted and may e. g. release dynamically allocated space.
The read and write operations enable the readers and writers to handle the complete nodes including all attributes, even those of user-defined types. The operation copy is needed in order to duplicate values of attributes of user-defined types. By default, ast just copies the bytes of an attribute in order to duplicate it. Therefore, pointer semantics is assumed for attributes of a pointer type. If value semantics is needed, the user has to take care about this operation. The operation equal checks whether two attributes are equal. It is used as atomic operation for the procedure that tests the equality of trees. The operation writeXML is used for XML output of attributes.

The operations are type specific in the sense that every type has its own set of operations. All attributes having the same type (target type name) are treated in the same way. If the target language permits type aliases, choosing different type names for one type introduces subtypes and allows to treat attributes of different subtypes differently. Type specific operations for the predefined types of a target language and for the types defined in the library reuse [Groa, Grob, Nas] are predefined within ast (see Appendices 9 to 13). For user-defined types, ast assumes default operations (see Table 4). The procedures yyReadHex and yyWriteHex read and write the bytes of an attribute as hexadecimal values. The procedures yyGet and yyPut read and write the bytes of an attribute unchanged (without conversion). The operations are defined by a macro mechanism. The procedure yyIsEqual checks the bytes of two attributes for equality. TYPE is replaced by the concrete type name. a is a formal macro parameter referring to the attribute. The predefined procedures mentioned in Table 4 use the global variable yyf of type FILE * (C, C++) [Grob] or IO.tFile.

</tr>
</tbody>
</table>

Note: In Java, the function of binary read/write is achieved via the serialization facility.
Tree-valued attributes are always of type tTREE in C, C++ and Modula-2 and so the same set of operations is used regardless of whether the attribute is declared to be of type tTREE or one of the node types. In Java there is a separate set of operations for each node type.

It is possible to redefine the operations by including new macro definitions in the GLOBAL section. The following example demonstrates the syntax for doing this. It shows how records of the type tPosition might be handled and how subtypes can be used to initialize attributes of the same type differently. Recall that ast already knows how to handle tPosition – what follows is only a demonstration.

**Example in C or C++:**

```c
IMPORT {
    #include "Sets.h"
    typedef struct { unsigned Line, Column; } tPosition;
    typedef tSet Set100;
    typedef tSet Set1000;
}

GLOBAL {
    # define beginPosition(a) a.Line = 0; a.Column = 0;
    # define readPosition(a) fscanf (yyf, "%d,%d", & a.Line, & a.Column);
    # define writePosition(a) fprintf (yyf, "%d, %d", a.Line, a.Column);
    # define beginSet100(a) MakeSet (& a, 100);
    # define closeSet100(a) ReleaseSet (& a);
    # define readSet100(a) ReadSet (yyf, & a);
    # define writeSet100(a) WriteSet (yyf, & a);
    # define beginSet1000(a) MakeSet (& a, 1000);
    # define closeSet1000(a) ReleaseSet (& a);
    # define readSet1000(a) ReadSet (yyf, & a);
    # define writeSet1000(a) WriteSet (yyf, & a);
}
```

(Modula-2) [Groa] or the static variables yyin of type de.cocolab.reuse.CocktailReader and yyout of type de.cocolab.reuse.CocktailWriter (Java) [Nas] describing the file used by the readers and writers.
Example in Modula-2:

IMPORT {
    FROM Sets IMPORT tSet;
    TYPE tPosition = RECORD Line, Column: CARDINAL; END;
    TYPE Set100 = tSet;
    TYPE Set1000 = tSet;
}

GLOBAL {
    FROM IO IMPORT ReadI, WriteI, WriteC;
    FROM Sets IMPORT MakeSet, ReleaseSet, ReadSet, WriteSet;
    # define beginPosition(a) a.Line := 0; a.Column := 0;
    # define readtPosition(a) a.Line := ReadI (yyf); a.Column := ReadI (yyf);
    # define writetPosition(a) WriteI (yyf, a.Line, 0); WriteC (yyf, ','); \ 
              WriteI (yyf, a.Column, 0);
    # define beginSet100(a) MakeSet (a, 100);
    # define closeSet100(a) ReleaseSet (a);
    # define readSet100(a) ReadSet (yyf, a);
    # define writeSet100(a) WriteSet (yyf, a);
    # define beginSet1000(a) MakeSet (a, 1000);
    # define closeSet1000(a) ReleaseSet (a);
    # define readSet1000(a) ReadSet (yyf, a);
    # define writeSet1000(a) WriteSet (yyf, a);
}

Example in Java:

```java
IMPORT {
    import de.cocolab.reuse.*; // including Set and Position
    // The C preprocessor is used within ast, so we can define
    // type aliases like this:
    # define Set100 Set
    # define Set1000 Set
}

GLOBAL {
    // Note in Java we have the type "Position" rather than "tPosition".
    # define beginPosition(a) a = new Position (0, 0);
    # define readPosition(a) a.line = yyin.readI (); a.column = yyin.readI ();
    # define writePosition(a) yyout.write (a.line); yyout.write (' '); \ 
        yyout.write (a.column);
    # define beginSet100(a) a = new Set (100);
    # define closeSet100(a) a = null;
    # define readSet100(a) a = readSet (yyin);
    # define writeSet100(a) writeSet (yyout, a);
    # define beginSet1000(a) a = new Set (1000);
    # define closeSet1000(a) a = null;
    # define readSet1000(a) a = readSet (yyin);
    # define writeSet1000(a) writeSet (yyout, a);
}

EXPORT {
    private Set readSet (CocktailReader in) {
        // code to read a set
    }
    private void writeSet (CocktailWriter out, Set s) {
        // code to write a set
    }
}

In the case of C++ the modules Idents and StringM of the library reuse [Grob] are implemented as classes. Thus several objects might be created from these classes. If attributes are declared with the types tIdent or tStringRef then ast will generate code that uses some methods of these classes. Now it has to be described to which of the objects a method call refers to. This is handled in the following way. The generated code looks like this:

```c
#ifndef Idents_PREFIX
    #include "Global.h"
    # define Idents_PREFIX gIdsents.
#endif

#ifndef String_PREFIX
    #include "Global.h"
    # define String_PREFIX gStringM.
#endif

Idents_PREFIX NoIdent;
Idents_PREFIX MakeIdent ( ... );
Idents_PREFIX WriteIdent ( ... );
String_PREFIX PutString ( ... );
String_PREFIX WriteString ( ... );
```
By default, the globally created objects `gIdents` and `gStringM` from the library `reuse` are used. This can be changed by providing definitions for the macros `Idents_PREFIX` and `String_PREFIX` in the GLOBAL section. Example:

```c
#include "Idents.h"
#include "StringM.h"

#define Idents_PREFIX my_idents_object.
#define String_PREFIX my_string_object->
	Idents my_idents_object;
	StringM * my_string_object = new StringM;
```

In the case of Java there is a similar consideration with respect to the `Ident` type and the associated `IdentTable` class [Nas]. The generated code looks like this:

```java
#ifdef Idents_PREFIX
#define Idents_PREFIX Global.idents.
#endif

Idents_PREFIX makeIdent (...);
```

The prefix is only needed when calling `makeIdent` to create a new `Ident` instance. All other operations are simply methods on an `Ident` object. By default, the statically created object `idents` from the library class `Global` is used. This can be changed by providing a definition for the macro `Idents_PREFIX` in the GLOBAL section. Example:

```java
GLOBAL {
    #define Idents_PREFIX my_idents_object.
}

EXPORT {
    static IdentTable my_idents_object = new IdentTable (100);
}
```

### 2.16. Attribute Initialization

An initial value for an attribute can be specified by a type specific operation as described in the previous chapter or by an attribute specific initializer expression. The latter is described by the following notation:

```plaintext
[ Name : Type := Expression ]
```

The expression is written in the syntax of the implementation language. It is evaluated at node creation time. Its value is assigned as initial value to the declared attribute. An attribute specific initializer takes precedence over a type specific initialization. An attribute specific initializer implies the property INPUT for this attribute. However, this attribute is not included in the list of parameters of the constructor procedure.

Example:

```plaintext
[ count : int := 0 ]
```
2.17. Storage Management

The storage management for the nodes to be created is completely automatic, by default. Usually, the user does not have to care about it. For Java the operation new is used for node allocation, deallocation is provided by the garbage collector. For proper C++ the operation new is used for node allocation, too, deallocation has to be done by explicit calls of the function ReleaseTREE which is based on the operation delete. For the languages C, simple C++, and Modula the predefined storage management works as follows: Every generated tree module contains its own heap manager which is designed in favour of speed. The constructor procedures use an in-line code sequence to obtain storage (see below). The heap manager does not maintain free lists. It only allows to free the complete heap of one module using the procedure ReleaseTREEModule. The procedure ReleaseTREE does not free the node space (except for proper C++), it only finalizes the attributes of the nodes. The predefined behaviour can be changed by including two macro definitions in the GLOBAL section.

For C the macros are initialized as follows:

```c
#define yyALLOC(size1, size2) \
(TREE_PoolFreePtr -= size1) >= TREE_PoolStartPtr ? \
(tTREE) TREE_PoolFreePtr : TREE_Alloc (size2)
#define yyFREE(ptr, size)
```

For simple C++ the macros are initialized as follows:

```c
#define yyALLOC(size1, size2) yyALLOCi (size1, size2)
#define yyFREE(ptr, size)
inline tTREE TREE::yyALLOCi (unsigned long yysize1, unsigned long yysize2) 
{ return TREE_PoolFreePtr >= TREE_PoolStartPtr + yysize1 ? 
(tTREE) (TREE_PoolFreePtr -= yysize1) : TREE_Alloc ((unsigned short) yysize2); } 
```

For Modula-2 the macros are initialized as follows:

```c
#define yyALLOC(ptr, size) ptr := yyPoolFreePtr; \
IF SYSTEM.ADDRESS (ptr) >= yyPoolMaxPtr THEN ptr := yyAlloc (); END; \ 
INC (yyPoolFreePtr, size);
#define yyFREE(ptr, size)
```

The following lines switch the heap manager to a global storage allocator with free lists:

```c
#define yyALLOC(size1, size2) (tTREE) Alloc (size2)
#define yyFREE(ptr, size) Free (size, ptr);
```

Now ReleaseTREE will work as expected whereas ReleaseTREEModule does not work any more.

In the cases of C and simple C++, the macro yyALLOC has two size arguments: While ‘size2’ specifies the number of bytes needed for the creation of a tree node, ‘size1’ specifies the corresponding aligned size. The aligned size ‘size1’ might be increased in comparison to ‘size2’ in order to fulfill the alignment requirements of the current machine. yyALLOC has to define an expression which yields a pointer to a storage area of at least ‘size2’ bytes. The macro yyFREE is used to indicate that ‘size’ bytes at the location ‘ptr’ can be released.

3. About the Generated Program Module

Ast is able to generate code for two types of target languages: procedural and object-oriented. For the procedural languages C and Modula-2 node types are mapped to members of a variant or
union type, and the generated procedures take an argument of this type. Procedure names are of the form Operation\text{TREE} where \text{TREE} is replaced by the tree module name, default \text{Tree}. The mapping for simple C++ is similar to the C mapping, and so it is described under the heading "Procedural Mapping".

For the object-oriented languages proper C++ and Java node types are mapped to classes and in general the procedures are methods applied to an instance and take no tree argument. Method names are of the form Operation or operation. As the names are within a name scope there is no need to qualify them with the name of the tree module.

Though the two schemes have much in common, there is enough difference to warrant separate descriptions.

3.1. Procedural Mapping

A specification is translated by \text{ast} into a program module consisting of a definition part and an implementation part. Only the definition part or header file respectively is sketched here – the Appendices 4, 5, and 7 contain the general schemes. The definition part contains primarily type declarations describing the structure of the tree nodes and the headings of the generated procedures.

Every non-abstract node type is turned into a constant declaration and a struct or record declaration. That is quite simple, because node types and record declarations are almost the same concepts except for the extension mechanism and some shorthand notations. All these records become members of a union type or a variant record used to describe tree nodes in general. This variant record has a tag field called \text{Kind} which stores the code of the node type. A pointer to the variant record is a type representing trees. Like all generated names, this pointer type is derived from the name of the specification. Table 5 briefly explains the exported objects (replace \text{TREE} by the name of the generated module (see section 2.9.) and <node type> by all the names of node types). In Modula-2 the names of the constants to code the node types and the names of the record variants are identical to the names of the node types. In other languages only the names of the union members are identical, the constant names are prefixed with the letter ’k’ standing for \text{Kind}.

In simple C++ a class named \text{TREE} is generated, additionally. All exported variables and procedures as well as the internal data structure are declared as members of this class. Thus it is possible to create and delete several tree objects which are independent from each other. This allows for a detailed control of memory usage, for example. In proper C++ a class named \text{yyTREE} is generated which serves as a base class for all node types.

The parameters of the procedures \text{m<node type>} have to be given in the order of the \text{input} attributes without initializer expression in the specification. Attributes of the base type (recursively) precede the ones of the derived type. The procedure \text{ForallTREE} allows for the execution of a procedure given as parameter for every element (node) of a list. Lists are indicated by the property \text{REVERSE} - the child with this property is the pointer to the succeeding list element. The procedures \text{TraverseTREE TD} and \text{TraverseTREE BU} visit all nodes of a tree or a graph respectively. At every node a procedure given as parameter is executed. An assignment of a tree or graph to a variable of type \text{iTREE} can be done in two ways: The usual assignment operators ‘=’ or ‘:=’ yield pointer semantics. The procedure \text{CopyTREE} yields value semantics by duplicating a given graph. The procedure \text{IsEqualTREE} is used to test structural equivalence of trees. It is not designed to handle general graphs.

The construction of the pointer and the union type above does not enforce the tree typing rules through the types of the target language. In fact, it is possible to construct trees that violate the

</tbody>
</table>

The user is responsible to adhere to the type rules. Most of the generated procedures do not care about the type rules. Moreover, type violations are possible and such erroneous trees are handled correctly by all procedures. The procedure CheckTREE can be used to check if a tree is properly typed. In case of typing errors the involved parent and child nodes are printed on standard error.

The binary graph writer procedure PutTREE produces a binary file containing the graph in linearized form. The nodes are written according to a depth first traversal. Edges are either represented by concatenation of nodes or by symbolic (integer) labels. The following kinds of records specified by C types are written to the output file:
# define yyNil 0374
# define yyNoLabel 0375
# define yyLabelDef 0376
# define yyLabelUse 0377

typedef unsigned char TREE_tKind; /* less than 252 node types */
typedef unsigned short TREE_tKind; /* more than 251 node types */
typedef unsigned short TREE_tLabel;

struct { char yyNil } NoTree;
struct { char yyLabelUse; TREE_tLabel <label>; } LabelUse;
struct { char yyLabelDef; TREE_tLabel <label>
           TREE_tKind Kind; <attributes> } LabelDef;
struct { char yyNoLabel; TREE_tKind Kind; <attributes> } NoLabel;
struct { char Kind; <attributes> } Kind;

Record fields whose name starts with yy have a constant value as defined. <label> is an integer representing a certain address. <attributes> are written with the type specific put macros which either copy the bytes of an attribute unchanged or do whatever the user has specified. If the value of the tag field Kind is less than 252 then the format Kind is used, otherwise the format NoLabel is used to write unlabeled nodes.

Graphs that have been written to a file with the procedure PutTREE can be read from file into memory with the procedure GetTREE.

The procedures WriteTREE and ReadTREE perform input and output of graphs similar to the procedures PutTREE and GetTREE. The differences are that a human readable text notation is used which causes the files to become considerably larger. The procedure WriteTREEXML performs output of a graph in XML format.

The procedure ConfigureTREE allows the configuration of some parameters of the tree module. It has two arguments of type string. The first argument describes the parameter and the second argument gives its value. Table 6 describes the possible parameters, the possible values, and the corresponding default values.

By default the procedure CheckTREE complains about children having the value NoTREE. If the parameter CheckReportNoTree is set to 0 then CheckTREE will allow children having the value NoTREE. Also, by default the procedure CheckTREE will output nodes that violate the typing rules using the procedure WriteTREENode. This can be switched off by setting the parameter CheckReportNodes to 0.

</table>

By default the procedure CheckTREE complains about children having the value NoTREE. If the parameter CheckReportNoTree is set to 0 then CheckTREE will allow children having the value NoTREE. Also, by default the procedure CheckTREE will output nodes that violate the typing rules using the procedure WriteTREENode. This can be switched off by setting the parameter CheckReportNodes to 0.
The parameters whose names start with the prefix Draw control some aspects of the graphical tree browser. The parameters DrawBoxHeight and DrawBoxWidth control the sizes of the rectangles denoting tree nodes. The horizontal and vertical distances between the nodes as well as the number of characters used to label a node are computed automatically depending on the size of a rectangle. The parameter DrawDepth controls to which depth tree nodes should be displayed. The parameter DrawLength controls to which length nodes in a list should be displayed. The parameter DrawFileName can be used to specify the name of the source file for a tree or graph.

By default, tree-valued attributes are treated like normal attributes: They are not traversed during any tree-traversing operations. By setting the parameter TreatTVAAsChild to 1 tree-valued attributes are treated like children in some of the I/O procedures: They are traversed and processed by the procedures ReadTREE, WriteTREE, GetTREE, and PutTREE. The support for changing the treatment of tree-valued attributes during runtime is provided by source code which is compiled conditionally. If this support for tree-valued attributes is needed it has to be enabled by defining the preprocessor symbol SUPPORT_TVA. This can be done either using a compiler option (-DSUPPORT_TVA, /DSUPPORT_TVA) or by including a directive in the IMPORT section:

```
#define SUPPORT_TVA
```

### 3.2. Object-Oriented Mapping

A specification is translated by ast into a program module consisting of a class declaration for every non-abstract node type. Only the public interfaces are sketched here – the Appendices 6 and 8 contain the general schemes.

Every non-abstract node type is turned into a constant declaration and a class declaration. That is quite simple, because node types and classes are the same concepts as are the extension mechanism and single inheritance (abstract node types are not mapped to classes and so we do not need multiple inheritance in the target language). All these classes have a common base class used to describe tree nodes in general. In proper C++, this class has a member called Kind which holds the code of the node type. In Java, this class has a method called yyKind which returns the code of the node type. A reference to the base class is a type representing trees. Like all generated names, this class type is derived from the name of the specification. Table 7 briefly explains the exported objects (replace TREE by the name of the generated module (see section 2.9.) and <node type> by all the names of node types). The names of the node classes are the same as in the specification, the constant names are prefixed with the letter 'k' standing for Kind.

The parameters of the constructors have to be given in the order of the input attributes without initializer expression in the specification. Attributes of the base type (recursively) precede the ones of the derived type. The procedure Forall/forall allows for the execution of a procedure given as parameter for every element (node) of a list. Lists are indicated by the property REVERSE - the child with this property is the reference to the succeeding list element. The procedures TraverseTD/traverseTD and TraverseBU/traverseBU visit all nodes of a tree or a graph respectively. At every node a procedure given as parameter is executed.

In C++, procedure parameters are implemented by function pointers. In Java, procedure parameters are implemented via an interface TREE.ProcTree which has a single method proc (TREE yyt). This method has no ‘throws’ clause, and so it is necessary to catch all exceptions that might be thrown by the code within the user procedure. If it is desired to retain the default action for exceptions thrown within such procedures then the following scheme may be used to ’hide’ the
Table 7: Generated Objects and Class Members

exception from the ProcTree interface.
import de.cocolab.reuse.MaskedException;
...
Tree t;
try {
    t.traverseTD (new Tree.ProcTree () {
        public void proc (Tree yyt) {
            try {
                // code which might throw an IOException
                yyt.writeNode (out);
            }
            catch (java.io.IOException e) {
                // wrap the exception in a MaskedException, which need not be caught
                throw new MaskedException (e);
            }
        }
    });
    } catch (MaskedException e) {
        // unwrap and rethrow exception, to get the usual stack trace and termination
        throw (java.io.IOException) (e.exception);
    }
}

An assignment of a tree or graph to a variable of type TREE can be done in two ways: The usual assignment operator '=' yields reference semantics. The procedure Copy/copy yields value semantics by duplicating a given graph.

The procedure IsEqual/isEqual is used to test structural equivalence of trees. It is not designed to handle general graphs.

The construction of the node classes enforces the tree typing rules through the types of the target language. Therefore, it is not possible to construct trees that violate the specification except by using NoTREE or null as a value for a child or by using type casts. The procedure Check/check can be used to check if a tree is properly constructed. In case of typing errors the involved parent and child nodes are printed on standard error.

The binary graph writer procedure Put/put produces a binary file containing the graph in linearized form. In proper C++ the same format is used as in the cases of C and simple C++. In Java this is implemented by object serialization.

Graphs that have been written to a file with the procedure Put/put can be read from file into memory with the procedure Get/get.

The procedures Write/write and Read/read perform input and output of graphs in human readable text notation. The user is responsible for making sure that appropriate macros or procedures are defined for converting any user defined attribute types to and from strings, see "Type Specific Operations".

The procedure Configure allows the configuration of some parameters of the tree module. For details see the chapter "Procedural Mapping".

3.3. Graph Browsers

The procedure QueryTREE/Query/query allows to browse a tree and to inspect one node at a time using an (old-fashioned) text user interface. A node including the names and the values of its attributes is printed on standard output. Then the user is prompted to provide one of the following commands from standard input:
parent  display parent node

goto <n>  display node at line number <n>

goto <n>  display node at line number <n>

quit  quit procedure

<selector>  display specified child (first match, abbreviation possible)

<selector><space>  display specified child (exact match, no abbreviation)

All commands can be abbreviated to an unambiguous prefix. Usually, a first match strategy is used to determine a child from its (abbreviated) selector name. With this search strategy, children whose name is a prefix of others may not be accessible. If an unabbreviated selector name is supplied together with a following space character an exact match strategy is used, which allows to access every child. The empty command behaves like parent.

The procedure DrawTREE/Draw provides a browser for trees and graphs with a graphic user interface. Nodes are displayed as labelled rectangles and edges (links to children) as arrows. A clearly arranged layout is calculated automatically. Attributes can be viewed similarly to QueryTREE/Query/query. The graphic browser provides scrolling, zooming, and direct access to the nodes using menu and mouse operations.

See the screenshot for an example of the browser window. It displays the abstract syntax tree (graph) for a sequence of three MiniLax statements. (The identifier skip denotes the call of a procedure.)

```
IF n < 0 THEN n := 1 ELSE skip END;
n := 2;
skip;
```

The nodes for the three statements are arranged underneath each other at the left-hand side. The children of the node If describe the condition, the THEN part, and the ELSE part of the IF statement. The children of the node Assign describe the left-hand side and the right-hand side of the assignment statement. The node Ident with the thick border has been selected. The attributes and children of this node are shown in a subwindow.

The procedure DrawTREE/Draw can be generated for the languages C, C++, and Modula-2. For compilation and linking the public domain package tcl/tk version 8.3 or higher is required. Under Unix linking is done with commands such as for example:

```
cc -L$X11/lib -ltk83 -ltcl83 -lX11 -lm -ldl .../libreuse.a  or  
cc -L$X11/lib -ltk8.3 -ltcl8.3 -lX11 -lm .../libreuse.a -ic
```

----------------------------------------------------------------------------

Zoom with the scale in the menu bar. Zooming is performed relative to the
center of the window. Zooming is logarithmic:

\[ \begin{align*}
2.0 &= 400 \% \\
1.0 &= 200 \% \\
0.0 &= 100 \% \\
-1.0 &= 50 \% \\
-2.0 &= 25 \%
\end{align*} \]

The labels of the nodes are the names of the node types.
They are truncated to the first characters in order to fit.
After opening a node the full information becomes visible in a subwindow.
Arrows at the right-hand side of a node or without a target node indicate
omitted subtrees. These arrows are called folding indicators.
By default, nodes to a maximal depth of 6 are shown.
For nodes in lists another limit with a default of 256 is valid.
These limits can be changed with the operation 'config' from the menu.
The new limits will be effective for all subsequent 'draw' operations.

The tree browser provides a call-back mechanism for the attributes shown in a subwindow.
There are tree-valued attributes and non-tree-valued attributes. Tree-valued attributes are marked
with the character '+'. A mouse click on a tree-valued attribute starts a new copy of the tree
browser on this subtree. A mouse click on a non-tree-valued attribute calls the macro \texttt{DrawAttr}
with two arguments: a pointer to the current node and a string giving the name of the selected attribute.
By default, this macro does nothing. It can be defined to execute arbitrary code. In the following
example the macro \texttt{DrawAttr} is defined to call the procedure \texttt{draw_attr}. This procedure decides
upon its arguments what to do and it may call for example another tree browser procedure named
\texttt{Drawmy_tree}.

GLOBAL {
#include "my_tree.h"
#define DrawAttr(addr, name) draw_attr (addr, name)

static void draw_attr (tTree tree, char * name)
{
    switch (tree->Kind) {
    case knode:
        if (strcmp (name, "attribute") == 0)
            Drawmy_tree (tree->node.attribute);
        break;
    }
}
}
4. Using the Generated Program Module

This section explains how to use the objects of the generated program module. Trees or graphs are created by successively creating their nodes. The easiest way is to call the constructor procedures `m<node_type>` or the constructor methods called `<node_type>`. These procedures and methods combine node creation, storage allocation, and attribute assignment. They provide a mechanism similar to record aggregates. Nested calls of constructor procedures allow programming with (ground) terms as in Prolog or LISP. In general, a node can be created by a call of one of the procedures

```
MakeTREE, n<node type>, or m<node type>.
```

or by invoking methods

```
TREE.make (k<node type>), <node type> (), <node type> (...).
```

The type of a node can be retrieved by examination of the predefined tag field/member variable called `Kind/kind`. Alternatively the function/member function `TREE_IsType/isType` can be used to test whether a node has a certain type or a subtype thereof. In the procedural languages children and attributes can be accessed using two record selections. The first one states the node type and the second one gives the selector name of the desired item. In object-oriented languages children and attributes are accessed directly, possibly after applying a type cast.

The following sections contain examples for the different implementation languages:
4.1. C

abstract syntax:

```
Expr = [Pos: tPosition] <
  IntConst = [Value] .
  RealConst = [Value: float] .
>
```

tree construction by a term:

```
#define Plus 1
#include "TREE.h"
tTREE t;
tPosition Pos;
t = mBinary (Pos, mIntConst (Pos, 2), mIntConst (Pos, 3), Plus);
```

tree construction during parsing:

```
Expr: '-' Expr {$$.Tree = mUnary ($1.Pos, $2.Tree, Minus); }.
Expr: IntConst {$$.Tree = mIntConst ($1.Pos, $1.IntValue); }.
Expr: RealConst {$$.Tree = mRealConst ($1.Pos, $1.RealValue); }.
```

tree construction using a statement sequence:

```
t = MakeTREE (kBinary);
t->Binary.Pos.Line = 0;
t->Binary.Pos.Column = 0;
t->Binary.Lop = MakeTREE (kIntConst);
t->Binary.Lop->IntConst.Pos = Pos;
t->Binary.Lop->IntConst.Value = 2;
t->Binary.Rop = MakeTREE (kIntConst);
t->Binary.Rop->IntConst.Pos = Pos;
t->Binary.Rop->IntConst.Value = 3;
t->Binary.Operator = Plus;
```

access of tag field, children, and attributes:

```
switch (t->Kind) {
  case kExpr : ... t->Expr.Pos ... 
  case kBinary: ... t->Binary.Operator ... 
           ... t->Binary.Lop ... 
  case kUnary : ... t->Unary.Expr->Expr.Pos ...
}
```
4.2. Simple C++

abstract syntax:

\[ \text{Expr} = \text{[Pos: tPosition]} \lt \text{Binary = Lop: Expr Rop: Expr [Operator: int].} \]
\[ \text{Unary = Expr [Operator].} \]
\[ \text{IntConst = [Value].} \]
\[ \text{RealConst = [Value: float].} \]

>.

tree construction by a term:

```cpp
#define Plus 1
#include "TREE.h"
TREE o; // create a tree object (manager)
tTREE t; // declare a pointer to tree nodes
tPosition Pos;
t = o.mBinary (Pos, o.mIntConst (Pos, 2), o.mIntConst (Pos, 3), Plus);
```

tree construction during parsing:

```cpp
Expr: ' - ' Expr {$.Tree = o.mUnary ($1.Pos, $2.Tree, Minus); } .
Expr: IntConst {$.Tree = o.mIntConst ($1.Pos, $1.IntValue); } .
Expr: RealConst {$.Tree = o.mRealConst ($1.Pos, $1.RealValue); } .
```

tree construction using a statement sequence:

```cpp
t = o.MakeTREE (kBinary);
t->Binary.Pos.Line = 0;
t->Binary.Pos.Column = 0;
t->Binary.Lop = o.MakeTREE (kIntConst);
t->Binary.Lop->IntConst.Pos = Pos;
t->Binary.Lop->IntConst.Value = 2;
t->Binary.Rop = o.MakeTREE (kIntConst);
t->Binary.Rop->IntConst.Pos = Pos;
t->Binary.Rop->IntConst.Value = 3;
t->Binary.Operator = Plus;
```

access of tag field, children, and attributes:

```cpp
switch (t->Kind) {
  case kExpr : ... t->Expr.Pos ... 
  case kBinary: ... t->Binary.Operator ... 
  ... t->Binary.Lop ... 
  case kUnary : ... t->Unary.Expr->Expr.Pos ...
}
```
4.3. Proper C++

abstract syntax:

```c++
Expr = [Pos: tPosition] <
  IntConst = [Value] .
  RealConst = [Value: float] .
>
```

tree construction by a term:

```c++
#define Plus 1
#include "TREE.h"
using namespace TREE; // allows IntConst instead of TREE::IntConst etc.
tTREE t; // declare a pointer to tree nodes of any type
Binary * b; // declare a pointer to tree nodes of type Binary
tPosition Pos;

b = new Binary (Pos, new IntConst (Pos, 2), new IntConst (Pos, 3), Plus);
```

tree construction during parsing:

```c++
Expr: '-'Expr {$$.tree = new Unary ($1.Pos, $2.tree, Minus); }.
Expr: IntConst {$$.tree = new IntConst ($1.Pos, $1.IntValue); }.
Expr: RealConst {$$.tree = new RealConst ($1.Pos, $1.RealValue); }.
```

tree construction using a statement sequence:

```c++
b = (tpBinary) Make (kBinary);
b->Pos.Line = 0;
b->Pos.Column = 0;
b->Lop = (IntConst *) Make (kIntConst);
b->Lop->Pos = Pos;
((IntConst *) b->Lop)->Value = 2;
b->Rop = new IntConst ();
b->Rop->Pos = Pos;
((tpIntConst) b->Rop)->Value = 3;
b->Operator = Plus;
```

access of tag field, children, and attributes:

```c++
switch (t->Kind) {
  case kExpr : ... ((tpExpr ) t)->Pos ... 
  case kBinary: ... ((tpBinary) t)->Operator ... 
                  ... ((tpBinary) t)->Lop ... 
  case kUnary : ... ((tpUnary ) t)->Expr->Pos ... 
}
```
4.4. Modula-2

abstract syntax:

Expr = [Pos: tPosition] <
Unary = Expr [Operator].
IntConst = [Value].
RealConst = [Value: REAL].

tree construction by a term:

CONST Plus = 1;
VAR t : tTREE;
   Pos: tPosition;
  t := mBinary (Pos, mIntConst (Pos, 2), mIntConst (Pos, 3), Plus);

tree construction during parsing:

Expr: ‘-’ Expr {$$.Tree := mUnary ($1.Pos, $2.Tree, Minus); }.
Expr: IntConst {$$.Tree := mIntConst ($1.Pos, $1.IntValue); }.
Expr: RealConst {$$.Tree := mRealConst ($1.Pos, $1.RealValue); }.

tree construction using a statement sequence:

  t := MakeTREE (Binary);
  t^.Binary.Pos.Line := 0;
  t^.Binary.Pos.Column := 0;
  t^.Binary.Lop := MakeTREE (IntConst);
  t^.Binary.Lop^.IntConst.Value := 2;
  t^.Binary.Rop := MakeTREE (IntConst);
  t^.Binary.Rop^.IntConst.Value := 3;

access of tag field, children, and attributes:

CASE t^.Kind OF
   | Expr : ... t^.Expr.Pos ... ...
   | Binary: ... t^.Binary.Operator ... ...
   | Unary : ... t^.Unary.Expr^.Expr.Pos ...
END;
4.5. Java

abstract syntax:

\[
\begin{align*}
\text{Expr} & = [\text{Pos: Position}] < \\
\text{Binary} & = \text{Lop: Expr} \text{ Rop: Expr} [\text{Operator: int}] . \\
\text{Unary} & = \text{Expr [Operator]} . \\
\text{IntConst} & = [\text{Value}] . \\
\text{RealConst} & = [\text{Value: float}] . \\
\end{align*}
\]

>.

tree construction by a term:

```java
import TREE.*; // allows IntConst instead of TREE.IntConst etc.
static final int Plus = 1;
de.cocolab.reuse.Position Pos;
Tree t = new Binary (Pos, new IntConst (Pos, 2), new IntConst (Pos, 3), Plus);
```

tree construction during parsing:

```java
Expr: Expr ‘+’ Expr {$$ = new Binary ($2.position (), $1.asExpr (), $3.asExpr (), Plus); }.
Expr: ‘-’ Expr {$$ = new Unary ($1.position (), $2.asExpr (), Minus); }.
Expr: IntConst {$$ = new IntConst ($1.position (), $1.asIntValue ().value); }.
Expr: RealConst {$$ = new RealConst ($1.position (), $1.asRealValue ().value); }.
```

tree construction using a statement sequence:

```java
Binary b = new Binary ();
b.Pos = new Position (0, 0);
b.Lop = new IntConst ();
b.Lop.Pos = Pos;
b.Lop.Value = 2;
b.Rop = new IntConst ();
b.Rop.Pos = Pos;
b.Rop.Value = 3;
b.Operator = Plus;
```

access of tag field, children, and attributes:

```java
switch (t.kind) {
    case TREE.Expr : Expr e = (Expr) t; ... e.Pos ... 
    case TREE.Binary: Binary b = (Binary) t; ... b.Operator ... 
                    ... b.Lop ... 
    case TREE.Unary : Unary u = (Unary) t; ... u.Expr.Pos ... 
}
```

5. Related Research

5.1. Variant Records

Ast specifications and variant record types like in Pascal or Modula-2 are very similar. Every node type in an ast specification corresponds to a single variant. In the generated code every node type is translated into a record type. All record types become members of a variant record type
representing the type for the trees.

The differences are the following: $Ast$ specifications are shorter than directly hand-written variant record types. $Ast$ specifications are based on the formalism of context-free grammars (see section 5.3.). The generator $ast$ automatically provides operations on record types which would be simple but voluminous to program by hand. The node constructor procedures allow to write record aggregates and provide dynamic storage management. The reader and writer procedures supply input and output for record types and even for complete linked data structures such as trees and graphs. Even when the target language is an object-oriented language such as Java, $ast$ still provides important advantages over hand coding.

5.2. Type Extensions

Type extensions have been introduced with the language Oberon [Wir88a, Wir88b, Wir88c]. The extension mechanism of $ast$ is basically the same as in Oberon. The notions extension, base type, and derived type are equivalent. Type extension is equivalent to inheritance in object-oriented languages such as C++ and Java. Type tests and type guards can be easily programmed by inspecting the tag field of a node. $Ast$ does not provide assignment of subtypes to base types in the sense of value semantics or a projection, respectively. The tool can be seen as a preprocessor providing type extensions for C, C++, and Modula-2.

The second example in section 2.5. illuminates the relationship between $ast$ and Oberon. The node type Stats is a base type with two fields, a child and an attribute. It is extended e. g. by the node type While with two more fields which are children.

5.3. Context-Free Grammars

As already mentioned, $ast$ specifications are based on context-free grammars. $Ast$ specifications extend context-free grammars by selector names for right-hand side symbols, attributes, the extension mechanism, and modules. If these features are omitted, we basically arrive at context-free grammars. This holds from the syntactic as well as from the semantic point of view. The names of the node types represent both terminal or nonterminal symbols and rule names. Node types correspond to grammar rules. The notions of derivation and derivation tree can be used similarly in both cases. The selector names can be seen as syntactic sugar and the attributes as some kind of terminal symbols. The extension mechanism is equivalent to a shorthand notation for factoring out common rule parts in combination with implicit chain rules.

Example:

$ast$ specification:

\[
\begin{array}{l}
\text{Stats} = \text{Next: Stats} < \\
\text{If} = \text{Expr Then: Stats} \text{ Else: Stats} . \\
\text{While} = \text{Expr Stats} . \\
> .
\end{array}
\]

corresponding context-free grammar:

\[
\begin{array}{l}
\text{Stats} = \text{Stats} . \\
\text{Stats} = \text{Stats If} . \\
\text{Stats} = \text{Stats While} . \\
\text{If} = \text{Expr Stats Stats} . \\
\text{While} = \text{Expr Stats} .
\end{array}
\]
In the example above, Stats corresponds to a nonterminal. There are two rules or right-hand sides for Stats which are named If and While. The latter would be regarded as nonterminals, too, if a child of types If or While would be specified.

5.4. Attribute Grammars

Attribute grammars [Knu68, Knu71] and ast specifications are based on context-free grammars and associate attributes with terminal and nonterminals symbols. Additionally ast allows attributes which are local to rules. As the structure of the tree itself is known and transparent, subtrees can be accessed or created dynamically and used as attribute values. The access of the right-hand side symbols uses the selector names for symbolic access instead of the grammar symbol with an additional subscript if needed. There is no need to map chain rules to tree nodes because of the extension mechanism offered by ast. Attribute evaluation is outside the scope of ast. This can be done either with the attribute evaluator generator ag [Grob] which understands ast specifications extended by attribute computation rules and processes the trees generated by ast or by hand-written programs that use an ast generated module. In the latter case attribute computations do not have to obey the single assignment restriction for attributes. They can assign a value to an attribute zero, one, or several times.

5.5. Interface Description Language (IDL)

The approach of ast is similar to the one of IDL [Lam87, NNG89]. Both specify attributed trees as well as graphs. Node types without extensions are called nodes in IDL and node types with extensions (base types) are called classes. Ast has simplified this to the single notion of a node type. Attributes are treated similarly in both systems. Children and attributes are both regarded as attributes, as structural and non-structural ones, with only little difference in between. Both systems allow multiple inheritance of attributes, ast has a separate syntax for single inheritance and uses the notion extension instead [Wir88a]. IDL knows the predefined types INTEGER, RATIONAL, BOOLEAN, STRING, SEQ OF, and SET OF. It offers special operations for the types SEQ OF and SET OF. Ast really has no built-in types at all, it uses the ones of the target language and has a table containing the type specific operations e.g. for reading and writing. Both ast and IDL allow attributes of user-defined types. In ast, the type specific operations for predefined or user-defined types are easily expressed by macros using the target language directly. IDL offers an assertion language whereas ast does not. IDL provides a mechanism to modify existing specifications. The module feature of ast can be used to extend existing specifications. From ast, readers and writers are requested with simple command line options instead of complicated syntactic constructs. Ast does not support representation specifications, because representations are much more easily expressed using the types of the target language directly. Summarizing, we consider ast to have a simpler specification method and to generate more powerful features like aggregates, reversal of lists, and graph browsers.

5.6. Attribute Coupled Grammars

Attribute coupled grammars (ACG’s) [Gie88] or algebraic specifications [HHK88] have only very little in common with ast specifications. They all view node types or rules as signatures of functions. The name of the node type plays the role of the function name and describes the result type. The types of the children and attributes correspond to the type of the function arguments. The constructor procedures generated by ast reflect this view best.
5.7. Object-Oriented Languages

The extension mechanism of \textit{ast} is exactly the same as single inheritance in object-oriented languages like e. g. Simula [DMN70] or Smalltalk [Gol84]. The hierarchy introduced by the extension mechanism corresponds directly to the class hierarchy of object-oriented languages. The notions base type and super class both represent the same concept. Messages and virtual procedures are out of the scope of \textit{ast}. Virtual procedures might be simulated with procedure-valued attributes. Table 8 summarizes the corresponding notions of trees (\textit{ast}), type extensions, and object-oriented programming.

5.8. Tree Grammars

Conventional tree grammars are characterized by the fact that all right-hand sides start with a terminal symbol. They are used for the description of string languages that represent trees in prefix form. \textit{Ast} specifications describe trees which are represented by (absolute) pointers from parent to child nodes. If we shift the names of node types of \textit{ast} specifications to the beginning of the right-hand side and interpret them as terminals we arrive at conventional tree grammars. That is exactly what is done by the \textit{ast} tree/graph writers. They write a tree in prefix form and prepend every node with the name of its node type. That is necessary to be able to perform the read operations.

6. Hints on Specifying Abstract Syntax

- Keep the abstract syntax as short and simple as possible.
- Try to normalize by representing only the most general form.
- Normalize to the general form e. g. by adding default values.
- Normalize several concrete representations to one abstract construct.
- Map concrete to abstract syntax by disregarding the concrete syntax rules and by concentrating on the semantic structure of the abstract syntax.
- Map several concrete nonterminals to one abstract node type (e. g. Expr, Term, and Factor \rightarrow Expr)
- Allow all lists to be empty regardless of the concrete syntax. Otherwise you have to process the list element at two places in exactly the same way. This causes programming overhead and violates the law of singularity: "One thing only once!"
- Operators can be represented by different node types (e. g. Plus, Minus, Mult, ...) or by one node type with an attribute describing the operator (e. g. Binary).

Table 8: Comparison of notions from the areas of trees, types, and object-oriented programming

</tbody>
</table>
- Lists can be represented by separate nodes for the list and the elements (e.g., Stats and Stat) or by nodes for the elements where every node has a child that refers to the next list element (see last example in section 2.12.1.).

7. Examples

The Appendices 1 to 3 contain examples of ast specifications.

Appendix 1 contains the concrete syntax of ast's specification language. The node types enclosed in quotes or starting with the character 't' constitute the terminals for ast's parser. The extensions and the node types used for the latter describe the lexical grammar.

Appendix 2 contains the concrete syntax of a small example programming language called MiniLAX [GrK88]. The attributes specified are the ones a parser would evaluate during parsing. The Appendices 1 and 2 show how concrete grammars can be described with ast.

Appendix 3 contains an abstract syntax for MiniLAX. The attributes specified are input or intrinsic ones whose values would be provided by the scanner and parser. The definition follows the hints of the previous section. Terminal symbols without attributes are omitted. All binary and unary operators are expressed by two nodes having one attribute to represent the operator. To simplify things as much as possible all lists are allowed to be empty and procedure declarations as well as calls always have a parameter list. The specification tries to keep the tree as small as possible. The inheritance mechanism allows to avoid all chain rules. There are no nodes for sequences of declarations, statements, etc. Instead every node for a declaration or a statement has a field named Next describing the successor entity. Except for expressions no separate nodes are used for identifiers. The information is included as attribute in the node types Proc, Var, Formal, and Call. The source position is stored only at the nodes where it might be needed during semantic analysis. The above measures not only reduce the amount of storage but they also reduce run time because less information has to be produced and processed.

8. Experiences

Ast can be used not only for abstract syntax trees in compilers but for every tree or graph-like data structure. In general the data structure can serve as interface between phases within a program or between separate programs. In the latter case it would be communicated via a file using the generated reader and writer procedures.

Generated tree respectively graph modules have successfully been used in compilers e.g. for MiniLAX [WGS89] and UNITY [Bie89] as well as for a Modula to C translator [Mar90]. The modules for the internal data structure of ast itself and the attribute evaluator generator ag [Grob] have also been generated by ast. Moreover, the symbol table module of the Modula to C translator has been generated.

The advantage of this approach is that it saves considerably hand-coding of trivial declarations and operations. Table 9 lists the sizes (numbers of lines) of some specifications and the generated modules. Sums in the specification column are composed of the sizes for the definition of node types and for user-supplied target code. Sums in the tree module column are composed of the sizes for the definition part and for the implementation part. The reason for the large sizes of the tree modules comes from the numerous node constructor procedures and from the graph browser in the case of ag. These procedures proved to be very helpful for debugging purposes as they provide readable output of complex data structures. The constructor procedures allow to write record aggregates. Therefore, node creation and assignment of values to the components can be written very compact. It is even possible to write (ground) terms as in Prolog or LISP by nested calls of the

9. Usage

NAME

ast - generator for abstract syntax trees

SYNOPSIS

ast [ -options ] ... [ +options ] [ -ldirectory ] [ files ]

DESCRIPTION

Ast generates a program module to handle arbitrary attributed trees and graphs. A typical application is the abstract syntax tree in a compiler. The input file contains a specification which describes the structure of all possible trees or nodes respectively and the attributes of the nodes. Ast generates type declarations to implement the tree and several procedures for tree manipulation including text and binary readers and writers (see options below). If file is omitted the specification is read from standard input.

OPTIONS

a  generate all except -ceh (default)

n  generate node constructors procedures n<node> (node)

m  generate node constructors procedures m<node> (make)

f  generate node/graph destroyer procedure ReleaseTREE (free)

F  generate general destroyer procedure ReleaseTREEModule (FREE)

O  generate text node writer procedure WriteTREENode (output)

R  generate text graph reader procedure ReadTREE

W  generate text graph writer procedure WriteTREE

+X generate XML graph writer procedure WriteTREEXML

g  generate binary graph reader procedure GetTREE

P  generate binary graph writer procedure PutTREE

t  generate top down traversal procedures TraverseTREETD (reverse depth first)
generate bottom up traversal (depth first) procedure TraverseTREEBU

R generate list reverser procedure ReverseTREE
R generate list iterator procedure ForallTREE
y generate graph copy procedure CopyTREE
= generate tree equality test procedure IsEqualTREE
k generate graph type checker procedure CheckTREE
q generate text graph browser procedure QueryTREE
e generate graphic graph browser procedure DrawTREE
_ generate array TREE_Name

generate header file or definition module
generate implementation part or module
generate import statements
generate lines not longer than 80 characters
generate tree/graph description in file TREE.TS
generate # line directives
touch output files only if necessary
report storage consumption
generate C source code (default: Modula-2)
generate simple C++ source code (using C data structure: union)
generate proper C++ source code (using C++ data structure: class)
generate Java source code
print help information

-l dir specify the directory dir where ast finds its tables
+H print advanced help
+E generate tree equality test procedure IsEqualTREE
+I suppress informations
+P generate empty bodies for procedures not selected

FILES

if output is in C:

<module>.h header file of the generated graph module
<module>.c body of the generated graph module
yy<module>.h macro file defining type specific operations
Tree.tcl procedure definitions for procedure DrawTREE

if output is in C++:

<module>.h header file of the generated graph module
<module>.cxx body of the generated graph module
yy<module>.h macro file defining type specific operations
Tree.tcl procedure definitions for procedure DrawTREE

if output is in Modula-2:

<module>.md definition module of the generated graph module
<module>.mi implementation module of the generated graph module
<module>.imp import statements

Tree.tcl procedure definitions for procedure DrawTREE

if output is in Java:

<module>.java classes of the generated graph module
